(Dated: August 27, 2014)

We study critical Casimir forces between planar walls and geometrically structured substrates within mean-field theory. As substrate structures, crenellated surfaces consisting of periodic arrays of rectangular crenels and merlons are considered. Within the widely used proximity force approximation, both the top surfaces of the merlons and the bottom surfaces of the crenels contribute to the critical Casimir force. However, for such systems the full, numerically determined critical Casimir forces deviate significantly from the pairwise addition formalism underlying the proximity force approximation. A first-order correction to the proximity force approximation is presented in terms of a step contribution arising from the critical Casimir interaction between a planar substrate and the right-angled steps of the merlons consisting of their upper and lower edges as well as their sidewalls.

I. INTRODUCTION

The thermodynamic analogue of the Casimir effect originating from the confinement of vacuum fluctuations [1, 2] is the critical Casimir effect due to the presence of long-ranged thermal fluctuations in a fluid close to its critical point at $T = T_c$. The corresponding critical Casimir forces have been predicted theoretically by Fisher and de Gennes in 1978 [3–6]. Experimentally, critical Casimir forces have been studied only during the last decade when first measurements were performed indirectly via monitoring the thickness of wetting films upon approaching a critical end point [7–11]. Later on, the critical Casimir force has been measured directly by using colloidal particles suspended in a binary liquid mixture [12–14].

Generically, the surfaces, which confine a binary liquid mixture, preferentially attract one of its two components leading to either positive [(+)] or negative [(-)] values of the scalar order parameter ϕ which describes the difference between the local concentration of one of the two components and its critical value. This generic preference of the surfaces confining the liquid can be described by effective surface fields. Upon approaching T_c , the critical adsorption profiles, which describe the concentration enhancement near the surface, become long ranged due to the concomitant divergence of the bulk correlation length [3, 15, 16]. In semi-infinite systems, the transition from the phase in which only the region near the single surface is ordered to the one in which also the bulk is ordered is known as the extraordinary or normal transition [17, 18]. For two surfaces opposing each other, depending on the mutual combinations of boundary conditions (BCs) critical Casimir forces are either attractive or repulsive. Their range is set by the bulk correlation length ξ . Whereas in fluids ξ is typically of molecular size, it attains values of the order of micrometers upon approaching the critical point [12–14]. Thus, critical fluctuations may induce effective interaction potentials with a strength of several $k_B T$ at the nanometer and micrometer scale. Moreover, critical Casimir forces are universal in character: due to the divergence of the correlation length molecular details of the confined binary liquid mixture

FIG. 1. Sketch of the geometry under consideration. An upper, planar wall is located at a minimal surface-to-surface distance L from a lower, parallel, crenellated wall which exhibits a periodic pattern with period P consisting of rectangular crenels of width W and depth D and merlons of width $P - W$ and height D . The system is spatially invariant in the y -direction. For later reference, the box at the bottom summarizes the definitions of the various scaling variables which the scaling function of the critical Casimir force depends on; t is the reduced temperature $t = (T - T_c)/T_c$ and ξ_0^+ is the nonuniversal amplitude of the bulk correlation length $\xi_+(t \rightarrow 0) = \xi_0^+ t^{-\nu}$ in the disordered phase, which defines the universal critical exponent ν .

become irrelevant and only a few gross features of the system determine the main characteristics of the critical Casimir forces [4–6].

In view of nano- and micro-electromechanical devices, nowadays various experimental techniques are available to endow solid surfaces with precisely defined geometrical or chemical structures (see, e.g., Refs. [19–23]). Critical Casimir forces for *chemically* structured confinements have been studied theoretically [24–31] as well as in experiments with colloidal particles [32, 33]. It has been demonstrated that such patterns induce *lateral* critical Casimir forces which can be used to trap particles reversibly along the lateral direction

‡ dietrich@is.mpg.de

in a designated way [32, 33]. Moreover, a suitable combination of attractive and repulsive critical Casimir forces may even lead to stable levitation [26, 27].

Here, we study critical Casimir forces for *geometrically* structured confinements. The quantum-electrodynamic Casimir effect in the presence of geometrically structured surfaces has been studied theoretically and experimentally for various surface topographies [34–39]. Two opposing surface gratings are subject to lateral quantum electrodynamic Casimir forces [35, 40–48]. In this context, experimental studies focus on spherical particles near crenellated surfaces, i.e., forming grooves with rectangular cross-sections [49–52]. Typically, the radius of the spherical particles is much larger than the period of the pattern of the crenellated surface such that, effectively, in the region of closest approach the system mimics the geometrical setup of a planar wall near a parallel, crenellated surface. Critical adsorption and critical Casimir forces for geometrically structured confinements have been studied for structures shaped as wedges and ridges with triangular cross-section [53–56], as well as for truncated wedges [57]. It was found that, for large distances between a sawtooth-shaped wall and a planar wall, the critical Casimir force effectively corresponds to the one between two planar walls; on the other hand, for short distances between the two surfaces, the tips of the ridges dominate the order parameter profile and the characteristic power law behavior of the critical Casimir force differs from that for planar surfaces [56].

The present study extends these previous investigations [53–56] into various directions. We consider a crenellated substrate close to a planar substrate at minimal surface-to-surface distance L , as shown in Fig. 1. The details of the geometry as well as the finite-size scaling of the critical Casimir phenomena are described in Section II. We calculate universal scaling functions for the critical Casimir forces and for the order parameter profiles within mean-field theory and for identical chemical BCs at both walls ($(+, +)$ configuration). In Section III we first study the universal features of the order parameter profiles close to T_c for the geometry under consideration. Second, in Section IV we study the critical Casimir forces acting on such geometrically structured substrates. Finally, in Section V we summarize our main findings.

II. FINITE-SIZE SCALING AND MEAN-FIELD THEORY

According to the theory of finite-size scaling, the singular contribution to the critical Casimir force is described by a universal scaling function, which is independent of the molecular details of the binary liquid mixture and depends only on the bulk universality class of the associated critical point [4, 5, 58, 59]. Here, we focus on the Ising universality class characterized by a scalar order parameter ϕ , which encompasses the experimentally relevant binary liquid mixtures and simple fluids. Upon approaching the critical point of the fluid, the bulk correlation length diverges as $\xi_{\pm}(t \rightarrow 0) = \xi_0^{\pm}|t|^{-\nu}$, where $\nu \simeq 0.63$ in spatial dimension $d = 3$ and $\nu = 1/2$ in spatial dimension $d = 4$ [60]; $\xi_0^{\pm}$ are nonuniversal amplitudes characterized by the universal ratio $\xi_0^+/\xi_0^- \simeq 1.9$ in $d = 3$ and $\xi_0^+/\xi_0^- = \sqrt{2}$ in $d = 4$. The sign of the reduced temperature $t = \pm(T - T_c)/T_c$ is chosen such that $t > 0$ corresponds to the mixed (disordered) phase of the fluid, whereas $t < 0$

corresponds to the ordered phase, corresponding to spontaneous phase separation. For an upper critical point the homogeneous phase is found at high temperatures, and one has $t = (T - T_c)/T_c$. However, many experimentally relevant binary liquid mixtures exhibit a lower critical point; in this case $t = -(T - T_c)/T_c$.

In general, the sign and the amplitude of the critical Casimir force depend on the types of effective chemical BCs at the walls and on the geometry of the confining surfaces. Here we focus on the case of equal, symmetry-breaking $(+)$ BCs, which corresponds to the generic case of preferential adsorption of one of the two species of a binary liquid mixture. This leads to an attractive critical Casimir force [61]. Inspired by experiments encompassing binary liquid mixtures of water and lutidine (with a lower critical point at $T_c \simeq 34^\circ\text{C}$) [12, 13, 32, 33], here a binary liquid mixture with a lower critical point is considered at fixed pressure and at its critical composition.

A. Planar walls

First, we briefly review the film geometry. In this case the liquid is confined between two parallel, macroscopically extended walls at a distance l . According to renormalization group theory the critical Casimir force $f_{\parallel}$ per area of one wall, which is acting on the parallel walls ($\parallel$), scales as [62–64]

$$f_{\parallel}(l, T) = k_B T \frac{1}{l^d} k_{\parallel}(t(l/\xi_0^+)^{1/\nu}). \quad (1)$$

The scaling function $k_{\parallel}$ depends only on a single scaling variable given by the film thickness l in units of $\xi_{\pm}$, raised to the power $1/\nu$. For equal chemical BCs, as discussed here, $k_{\parallel}$ is negative, so that the critical Casimir force is attractive. For $T \rightarrow T_c$ the scaling function of the critical Casimir force reduces to a universal constant value, the so-called critical Casimir amplitude [4, 5]:

$$k_{\parallel}(0) = \Delta_{(+,+)}. \quad (2)$$

Accordingly, at T_c the critical Casimir force decays algebraically $\propto k_B T_c \Delta_{(+,+)}/l^d$. Away from criticality, the critical Casimir force decays exponentially as a function of $l/\xi_{\pm}$. The scaling function $k_{\parallel}$ has been calculated exactly in $d = 2$ [65], for $d \leq 4$ using a perturbative field-theoretical method [61] or a local-functional method [66], and in $d = 3$ numerically via Monte Carlo simulations [67–71].

B. Crenellated walls

In the following we consider a crenellated wall located at a minimal surface-to-surface distance L from a planar wall as sketched in Fig. 1. The width and depth of the crenels are given by W and D , respectively, and the structure is periodic along the lateral x -direction with period P , so that the width of the merlons, i.e., the surface-to-surface separation between two neighboring crenels, is given by $P - W$. Accordingly, the corresponding universal contribution to the critical

Casimir force f per area of the planar wall scales as

$$f(L, D, W, P, T) = k_B T \frac{1}{L^d} k(\tau, \delta, \omega, \lambda), \quad (3)$$

where the geometrical parameters form the following scaling variables:

$$\tau \equiv t \left(\frac{L}{\xi_+} \right)^{1/\nu}, \quad \delta \equiv \frac{D}{L}, \quad \omega \equiv \frac{W}{L}, \quad \lambda \equiv \frac{W}{P} \in (0, 1). \quad (4)$$

The critical Casimir force between a crenellated and a planar wall attains the value of the corresponding force between two planar walls in various limits. For very shallow crenels, i.e., in the limit $D \ll L$ or $\delta \rightarrow 0$, the following relation holds:

$$k(\tau, \delta, \lambda, \omega) \xrightarrow{\delta \rightarrow 0} k_{\parallel}(\tau). \quad (5)$$

As will be discussed in more detail below, we find that for narrow crenels with $\omega = W/L \rightarrow 0$, the order parameter profile attains the form of the planar wall geometry, *independent* of the value of δ :

$$k(\tau, \delta, \lambda, \omega) \xrightarrow{\omega \rightarrow 0} k_{\parallel}(\tau). \quad (6)$$

Similarly, for $\lambda \rightarrow 0$, one has

$$k(\tau, \delta, \lambda, \omega) \xrightarrow{\lambda \rightarrow 0} k_{\parallel}(\tau). \quad (7)$$

For very broad crenels compared with the film thickness, i.e., $\omega \rightarrow \infty$, the limiting behavior of the scaling function of the critical Casimir force is given by the average of the scaling functions for two planar walls at distances L and $L + D$, respectively. This corresponds to the so-called proximity force approximation (PFA), which we discuss in the following. Within the PFA the surfaces are subdivided into infinitely small elements parallel to each other, and the resulting force is obtained by pairwise adding the individual contributions to the force. The Derjaguin approximation is a special case of the PFA for smoothly curved surfaces. Detailed comparisons of the Derjaguin approximation with experimental and theoretical results revealed a good agreement for a large range of parameters [12, 13, 33]. For the present geometry the resulting critical Casimir force f^{PFA} per area [Eq. (3)] acts along the z -direction and is the sum of two contributions: (i) the force between the fraction $(1 - \lambda)$ of the upper flat wall and the top surfaces of the merlons separated by the distance L , and (ii) the force between the fraction λ of the upper flat wall and the bottom surfaces of the crenels separated by the distance $L + D$:

$$f^{\text{PFA}}(L, D, W, P, T) = (1 - \lambda) f_{\parallel}(L, T) + \lambda f_{\parallel}(L + D, T). \quad (8)$$

Accordingly, the scaling function of the critical Casimir force within the PFA is given by

$$k^{\text{PFA}}(\tau, \delta, \lambda) = (1 - \lambda) k_{\parallel}(\tau) + \frac{\lambda}{(1 + \delta)^d} k_{\parallel}(\tau(1 + \delta)^{1/\nu}). \quad (9)$$

The scaling function k^{PFA} is independent of ω because within PFA the effective interactions between the steps and the upper wall are ignored. That is, as long the values of λ and δ are fixed, steps may be arbitrarily added to or removed from

FIG. 2. Sketch concerning the limiting behavior of the scaling function k (Eq. (10)) for $\omega = W/L \gg 1$ at fixed values of $\lambda = W/P$ and $\delta = D/L$. (a) The surfaces of the lower, geometrically structured substrate which are parallel to the film (indicated by a green line) give rise to the PFA contribution k^{PFA} to the universal scaling function k of the critical Casimir force. In the limit $\omega \rightarrow \infty$, the steps consisting of the upper and lower edges as well as the sidewalls (indicated by the red lines and dots) generate the step contribution $A(\tau, \delta, \lambda)/\omega$ to the critical Casimir force (see Eq. (10)). For fixed $0 < \lambda < 1$, the step-step interaction vanishes and A becomes independent of λ . (b) For $\delta \gg 1$ the step contribution A/ω to the critical Casimir force effectively corresponds to the contribution of two right-angled corners opposite to a planar substrate and attains a limiting value independent of δ .

the structured substrate (e.g., via a transformation $W \mapsto \alpha W$ and $P \mapsto \alpha P$, where $\alpha > 0$) without changing the force within PFA, independent of the value of ω . Analogous to the case of chemically striped surfaces, discussed in detail in Refs. [28–30], every isolated geometrical step gives rise to a contribution to the scaling function of the critical Casimir force per area which is proportional to $\omega^{-1} = L/W$. The asymptotic behavior for $\omega \rightarrow \infty$ of the universal scaling function for the critical Casimir force between a planar wall and a crenellated surface is therefore given by

$$k(\tau, \delta, 0 < \lambda < 1, \omega \rightarrow \infty) = k^{\text{PFA}}(\tau, \delta, \lambda) + \frac{A(\tau, \delta, \lambda)}{\omega}, \quad (10)$$

where we define $A(\tau, \delta, \lambda)$ as the universal contribution of a pair of geometrical steps as sketched in Fig. 2(a). For a fixed value $0 < \lambda < 1$, in Eq. (10) A actually does not depend on λ because in the limit $\omega \rightarrow \infty$ the distance L between the steps and the upper wall is much smaller than the step-step distances W and $P - W$, respectively, so that step-step interactions are negligible in this limit. In the following we therefore define $A(\tau, \delta) \equiv A(\tau, \delta, 0 < \lambda < 1)$ and consider this as the generic case. For very deep crenels $A(\tau, \delta \rightarrow \infty)$ attains a τ -dependent value which corresponds to the contribution to the critical Casimir force between a pair of top corners of the right-angled edges of the merlons opposite to a planar wall (see the sketch in Fig. 2(b)).

C. Mean-field theory

The standard Landau-Ginzburg-Wilson fixed-point effective Hamiltonian describing critical phenomena of the Ising bulk universality class is given by [15, 16, 72]

$$\mathcal{H}[\phi] = \int_V d^d r \left\{ \frac{1}{2} (\nabla \phi)^2 + \frac{\hat{\tau}}{2} \phi^2 + \frac{u}{4!} \phi^4 - h \phi \right\}, \quad (11)$$

where $\phi(\mathbf{r})$ is proportional to the order parameter describing the fluid, which completely fills the accessible volume V in d -dimensional space. The statistical weight of a configuration $\phi(\mathbf{r})$ is proportional to $\exp(-\mathcal{H})$. The parameter $\hat{\tau}$ in Eq. (11) is proportional to t , and $u > 0$ is a coupling constant. The last term in Eq. (11) vanishes for the case considered here (i.e., $h = 0$), which corresponds to the situation that the concentrations of the species forming the binary liquid mixture are fixed to their critical values. In a finite-size system the bulk Hamiltonian $\mathcal{H}[\phi]$ is supplemented by appropriate surface and curvature (edge) contributions [15, 16, 72, 73]. This surface contribution, which adds to Eq. (11), is given by [15, 16, 72, 73]

$$\mathcal{H}_s[\phi] = \int_{\partial V} d^{(d-1)} r \left\{ \frac{c}{2} \phi^2 - h_1 \phi \right\}, \quad (12)$$

where c is the so-called surface enhancement and h_1 is a surface field; ∂V is the surface of the volume V . In the strong adsorption limit [18, 74], as discussed in the present study, these contributions generate boundary conditions for the order parameter such that $\phi|_{\text{surface}} = \infty$ corresponding to (+) BCs. Thus, the use of Eq. (12) together with additional surface contributions can be replaced by applying the appropriate BC to ϕ and by using Eq. (11) throughout the bulk. The mean-field order parameter profile minimizes the Hamiltonian, i.e., $\delta \mathcal{H}[\phi] / \delta \phi|_{\phi=\langle \phi \rangle} = 0$. In the *bulk*, the mean-field order parameter is spatially constant and attains the values $\langle \phi \rangle_b = \pm B|t|^\beta$ for $t < 0$ and $\langle \phi \rangle = 0$ for $t > 0$, where, besides ξ_0^+ , B is the only additional independent nonuniversal amplitude appearing in the description of bulk critical phenomena; $\beta(d=4) = 1/2$ is a standard critical exponent. Within mean-field theory (MFT) the following relations hold: $\hat{\tau} = t(\xi_0^+)^{-2}$ and $u = 6B^{-2}(\xi_0^+)^{-2}$.

For the film geometry, the MFT scaling function for the critical Casimir force can be determined analytically [61]. One finds [see Eq. (2)] for the case of the same strong adsorption at both surfaces the critical Casimir amplitude $\Delta_{(+,+)} = 24[K(1/\sqrt{2})]^4/u \simeq -283.61 \times u^{-1}$, where K is the complete elliptic integral of the first kind [61]. Renormalization group arguments tell that MFT provides the correct universal properties of critical phenomena for spatial dimensions above the upper critical dimension, i.e., $d \geq d_{uc} = 4$, up to logarithmic corrections in $d = d_{uc}$ [75]. Moreover, MFT provides the lowest-order contribution to universal quantities within an expansion in terms of $\varepsilon = 4 - d$.

FIG. 3. Rescaled MFT order parameter profile $m(\mathbf{r}) \times L$ (see Eqs. (16) and (17)) at $T = T_c$ (i.e., $\tau = 0$) for various values of $\delta = D/L$ and $\omega = W/L$ with $\lambda = 1/2$ fixed (see Fig. 1): (a) $\delta = \omega = 1$ (deep crenels and widely spaced merlons), (b) $\delta = 0.2$, $\omega = 1$ (shallow crenels and widely spaced merlons), and (c) $\delta = \omega = 1/3$ (shallow crenels and closely spaced merlons). The local values of $m(\mathbf{r}) \times L$ are indicated by the color code given by the side bars. Large values of $m \times L \gg 1$ indicate strong adsorption of the fluid close to the surfaces. From the shape of the contour lines for $m \times L = 6$ near the structured wall (lower white lines) the dependence of the critical adsorption profile on the scaling variables δ and ω is clearly visible. Whereas for widely spaced merlons with $\omega = 1$ the adsorption profile follows the shape of the crenelated surface, for closely spaced merlons with $\omega = 1/3$ the crenels are filled with the adsorbed fluid and for increasing normal distances $z > 0$ the order parameter profile rapidly adopts an effective planar wall behavior corresponding to rather straight contour lines.

III. ORDER PARAMETER PROFILES

The order parameter ϕ exhibits the following scaling properties (see Subsec. 2.5 in Ref. [28]):

$$\phi(t, x, z, L; D, W, P) = B|t|^\beta Q_\pm\left(\frac{x}{\xi_\pm}, \frac{z}{\xi_\pm}, \frac{L}{\xi_\pm}; \delta, \omega, \lambda\right) \quad (13)$$

or equivalently

$$\phi(t, x, z, L; D, W, P) = B\left(\frac{L}{\xi_0^+}\right)^{-\beta/\nu} R_\pm\left(\frac{x}{L}, \frac{z}{L}, \tau; \delta, \omega, \lambda\right) \quad (14)$$

with universal scaling functions $Q_\pm$ and $R_\pm$. The bulk order parameter varies as $\phi_b = B|t|^\beta$. This implies

$$\left(\frac{L}{\xi_0^+}\right)^{\beta/\nu} \frac{1}{B} \phi(\mathbf{r}) = R_\pm\left(\frac{x}{L}, \frac{z}{L}, \tau; \delta, \omega, \lambda\right). \quad (15)$$

Within MFT one has $\beta = \nu = 1/2$ so that with the definition

$$m(\mathbf{r}) \equiv (B\xi_0^+)^{-1} \langle \phi(\mathbf{r}) \rangle \quad (16)$$

Eq. (15) renders the following MFT approximation for the scaling function R :

$$m(\mathbf{r}) \times L = R^{\text{MFT}}\left(\frac{x}{L}, \frac{z}{L}, \tau; \delta, \omega, \lambda\right). \quad (17)$$

In the following we present these MFT results which we have obtained by minimizing numerically $\mathcal{H}[\phi]$ using a finite element method in order to obtain the (spatially inhomogeneous) profile $m(\mathbf{r})$ for the geometries under consideration. Here, we focus on the case of strong adsorption and the same chemical BCs at the two surfaces. For distances from the surface of a substrate which are small compared to $\xi_\pm$, or for $T \rightarrow T_c$, the order parameter varies algebraically. In order to obtain a BC for the numerical calculations we use a short distance expansion (see, e.g., Ref. [56] and reference therein) with $m = \infty$ at the surfaces of the two walls shown in Fig. 1.

In Fig. 3 the order parameter profile of a fluid confined between a planar and a crenellated wall at the bulk critical point $T = T_c$ is shown for $\lambda = W/P = 0.5$; $m(\mathbf{r})$ depends on x and z and is invariant along the y -direction. From Fig. 3 we can infer that for $\omega = W/L = 1$ the order parameter profile follows the shape of the crenellated surface [Figs. 3 (a) and (b)], whereas for $\omega = 1/3$ the space between the merlons corresponds to high values of the order parameter, i.e., the crenels are “filled” with the adsorbed fluid [Fig. 3 (c)] until an almost straight contour line has formed separating the fluid with high order parameter, which fills the crenels, from the fluid with lower order parameter in the middle of the slit. Hence for narrow crenels, for increasing $z > 0$ the order parameter profiles rapidly approach the ones of a corresponding film of thickness L .

IV. SCALING FUNCTION OF THE CRITICAL CASIMIR FORCE

The critical Casimir forces are calculated directly from the numerically obtained mean-field order parameter profiles using the stress tensor [61, 76]. As in Sec. III, here throughout

FIG. 4. Normalized scaling function $k(\tau, \delta, \omega, \lambda)/|\Delta_{(++)}|$ of the critical Casimir force as a function of $\tau = t(L/\xi_0^+)^{1/\nu}$ for a fixed ratio $\lambda = W/P = 0.5$ and various values of $\delta = D/L$ and $\omega = W/L$. In addition to the numerically obtained full MFT scaling functions (full curves), the corresponding scaling functions k^{PFA} obtained within the PFA [Eq. (9)] (dashed curves) and the scaling function for two planar walls (PW) at distance L (dashed-dotted curves) are shown. For $\delta = \omega = 1$, in (a) the MFT scaling function does neither agree with the one obtained within PFA nor with the one for the PW case, but lies roughly in between these two curves. However, for shallow crenels and widely spaced merlons with $\delta = 0.2$ and $\omega = 1$, in (b) the PFA is closer to the full MFT scaling function. For shallow crenels and closely spaced merlons with $\delta = \omega = 1/3$, in (c) the full MFT scaling function is similar to the one for two planar walls (PW). Figures 3 and 4 allow a direct comparison between the order parameter distribution and the critical Casimir force at T_c , i.e., for $\tau = 0$. Here the scaling function k is normalized with $|\Delta_{(++)}|$ so that the ratio does not depend on the coupling constant u , which within MFT is undetermined.

we focus on the case $\lambda = W/P = 0.5$. We estimate the numerical error of the present method to be less than 1%.

In Fig. 4 the scaling function $k(\tau, \delta, \omega, \lambda)$ of the critical Casimir force is shown as a function of $\tau = t(L/\xi_0^+)^{1/\nu}$ for various values of $\delta = D/L$ and $\omega = W/L$. In addition to the numerically obtained full MFT scaling functions (solid curves), the corresponding scaling functions $k^{\text{PFA}}(\tau, \delta, \omega, \lambda)$ obtained within the PFA [Eq. (9)] (dashed curves), and the

FIG. 6. (a) Normalized amplitude $A(\tau, \delta)/|\Delta_{(+, +)}|$ [see Eq. (10)] of the step contribution to the critical Casimir force for $\tau = 0$ as a function of the reduced depth $\delta = D/L$ of the crenels. For $\delta \gtrsim 5$ a plateau value $A(\tau = 0, \delta \rightarrow \infty)/|\Delta_{(+, +)}| \simeq -0.367$ is reached and the step contribution to the critical Casimir force becomes independent of the depth of the crenels. In (b) $A(\tau, \delta)/|\Delta_{(+, +)}|$ is shown as a function of τ as obtained for $\delta = 5$. According to our analysis, for $\delta = 5$ the limiting behavior for $\delta \rightarrow \infty$ is almost reached (see (a)). (According to Eq. (10) A does not depend on λ as long as the value of the latter is not 0 or 1.)

are displaced such that the minimum of A as a function of τ is located closer to the critical point at $\tau = 0$. For comparison we note that the functional shape of the amplitude of the step contribution is very close to the numerically obtained MFT scaling function of the attractive critical Casimir force acting between a thin cylinder and a planar substrate, where the symmetry axis of the cylinder is parallel to the substrate [31]. Indeed, the lower white contour line in Fig. 3(a) indicates that one may approximate each cross-section of the two right-angled edges of the merlons by a small inscribed quarter circle, keeping in mind that in the limit $\xi_{\pm}/R \rightarrow \infty$ the critical adsorption profile near a thin cylinder is independent of the radius R of the cylinder [77].

V. CONCLUSIONS

Within mean field theory (MFT) we have calculated the critical Casimir force between a planar and a crenellated surface, i.e., a periodic structure of geometric steps forming crenels and merlons (Fig. 1). To this end we have numerically calculated the critical order parameter profiles of a fluid confined by such a structure. We have focused on the experimentally relevant case of binary liquid mixtures or simple liquids,

which belong to the Ising bulk universality class, and on (+) boundary conditions (BCs) which correspond to the generic case of strong critical adsorption. Using the stress tensor we have calculated the universal scaling function of the singular contribution to the critical Casimir force, acting on the confining walls along the normal direction upon approaching the critical point. We have obtained the following main results:

1. According to finite size scaling, the universal scaling function of the critical Casimir force depends on only a few scaling variables which describe the geometry under consideration [Eqs. (3), (4), and Fig. 1]. In the limits, that the width W or the depth D of the crenels are small compared to the film width or the period of the geometric structure, the force reduces to the one acting between two parallel flat substrates at a distance L [Eqs. (5) – (7)]. On the other hand, for fixed reduced crenel depth δ and for reduced crenel width $\omega = W/l \rightarrow \infty$, the expression for the critical Casimir force approaches the one obtained via the proximity force approximation (PFA) [Eq. (8)] as $A(\tau, \delta, \lambda)/\omega$, which can be interpreted as a step contribution [see Eq. (10) and Fig. 2].
2. In Sec. III we have shown generic examples of order parameter profiles (i.e., the universal contribution to the profiles of the deviations of the local concentration or density from its critical value in the bulk) as obtained within MFT at the critical point. Whereas for crenel sizes comparable with the film thickness the order parameter profile follows the geometrical structure [Figs. 3(a) and (b)], for shallow crenels and closely spaced merlons the order parameter profile resembles the one in between two planar walls [Fig. 3(c)]. In this latter case strong critical adsorption effectively suppresses the influence of the merlons.
3. These properties of the order parameter profiles agree with our results for the universal scaling function k [Eq. (3)] of the critical Casimir force presented in Section IV: For deep crenels and widely spaced merlons the full MFT scaling function of the critical Casimir force as a function of the scaling variable τ does neither agree with the planar wall limit (PW) nor with the PFA [Fig. 4(a)]. On the other hand, for shallow crenels and widely spaced merlons the PFA describes the actual full MFT behavior better [Fig. 4(b)], whereas for shallow crenels and closely spaced merlons the PW limit is approached [Fig. 4(c)]. Thus, depending on the values of the scaling variables $\delta = D/L$ and $\omega = W/L$, the critical Casimir force interpolates between its limiting behaviors described by the PFA, which always underestimates the strength of the force, and the PW limit, which overestimates the critical Casimir force. This can also be seen in Fig. 5(b) which shows the ratio of the universal scaling function of the critical Casimir force and its corresponding PFA value as a function of δ .
4. Upon increasing ω the scaling function k^{PFA} as obtained within PFA is approached as $A(\tau, \delta, \lambda)/\omega$ [Fig. 5(a)], which can be interpreted as a step contribution with $A(\tau, \delta) \equiv A(\tau, \delta, 0 < \lambda < 1)$ de facto independent of λ [Eq. (10)]. Thus, for widely spaced merlons the critical

Casimir force can be described as the linear superposition of the planar wall contributions at distances L and $L + D$, respectively, plus additional step contributions stemming from the geometrical steps. For large values of δ this step contribution approaches a specific negative value, independent of the crenel depth D [Fig. 6(a)].

To conclude, our numerical calculations within MFT extend previous investigations of the critical Casimir force caused by the confinement due to structured substrates. In particular, we have analyzed in detail the crossover of the universal scaling function of the critical Casimir force from an effective planar wall limit for small roughness to the PFA limit. This may not only be useful for the analysis of critical Casimir forces in such experimentally relevant, designed geometries, but could also help in understanding unavoidable roughness

corrections in the case of planar geometries. Moreover, our results show that the first-order correction to the PFA can be expressed in terms of a contribution stemming from the individual geometrical steps. This is analogous to similar situations involving chemically structured surfaces [29], which are discussed in Ref. [30]. For comparison we note that such step contributions arising from crenellated surfaces are also of importance for non-critical fluids consisting of rod-like particles close to the isotropic to nematic phase transition of the bulk fluid [78].

ACKNOWLEDGMENTS

The authors thank Nikolas Brunner for very helpful contributions.
